Introduction and Problem Formulation

This notebook investigates how different execution strategies affect the performance of stochastic gradient descent (SGD), focusing on system-level behaviour rather than improvements in model predictive performance.

The objective is to analyse execution-level performance characteristics while keeping algorithmic components fixed, allowing system-level effects to be isolated.

Abstract

This notebook investigates how different execution strategies influence the system-level performance of stochastic gradient descent (SGD) while maintaining identical algorithmic behaviour. The analysis compares serial execution, shared-memory parallelism using lock-free updates, and distributed data-parallel training with periodic model averaging. Evaluation focuses on execution efficiency, scalability behaviour, synchronization overhead, and practical runtime constraints.

Initial observations revealed differences between theoretical expectations of parallel speedup and observed performance, motivating additional experiments exploring scaling behaviour, communication frequency, and workload sensitivity. Results highlight that effective scalability depends not only on algorithm design but also on workload characteristics, execution environment, and system architecture, emphasizing the importance of systems-level thinking in machine learning workflows.

Experiment Evolution Overview

This notebook follows an iterative experimental workflow derived from the initial design proposed in Assignment 1. Rather than presenting independent implementations, the experiments are organized as successive design stages to evaluate how execution strategies influence system-level performance.

The experimental process evolves through multiple design versions:

- **Version 0 (Initial Design):** Serial SGD baseline used as a reference for performance measurement.
- **Version 1:** Shared-memory parallel implementation inspired by lock-free updates (HOGWILD-style).
- **Version 2:** Distributed data-parallel implementation with periodic synchronization.

- **Version 3:** Additional investigative experiments introduced after observing unexpected performance behaviour, including scaling analysis and synchronization frequency studies.

The objective is to understand how practical system constraints affect theoretical expectations about parallel scalability and execution efficiency.

The following section presents a structured overview of the notebook organization, outlining how these design stages are implemented throughout the experimental workflow.

How to Read This Notebook

This notebook follows a structured experimental progression designed to analyze system-level behaviour of stochastic gradient descent (SGD) under different execution strategies. Rather than presenting independent experiments, each section builds upon observations from previous stages.

Early sections introduce the experimental setup and baseline implementation. Subsequent sections progressively extend the execution model from serial training to shared-memory parallelism and distributed data-parallel simulation. Later analysis sections investigate scalability behaviour and execution trade-offs motivated by earlier experimental observations.

Some sections may appear conceptually related (for example, design overview versus retrospective analysis). This is intentional: early sections describe the planned experimental workflow, while later sections reflect on completed experiments to derive systems-level insights.

Readers may follow the notebook sequentially to observe how design decisions evolve through experimentation, or navigate directly to implementation or analysis sections depending on interest.

Notebook Structure Overview

This notebook follows a structured experimental workflow designed to analyse system-level behaviour of stochastic gradient descent (SGD) under different execution strategies. The organization reflects a progressive design evolution in which each implementation stage builds upon prior observations to investigate execution efficiency, scalability, and system-level trade-offs.

The notebook is organised as follows:

Introduction and Problem Formulation

Defines the motivation, scope, and objectives of analysing execution strategies from a systems perspective, emphasizing execution behaviour rather than predictive performance improvements.

Abstract

Provides a concise overview of experimental goals, methodology, and key insights derived from the study.

Experiment Evolution Overview

Introduces the iterative experimental design and explains how execution strategies evolve across multiple implementation stages.

How to Read This Notebook

Guides readers through the intended workflow and explains how experimental sections build upon one another to support progressive analysis.

Experimental Design and Setup

Establishes controlled experimental conditions, including:

- Reproducibility configuration
- Experimental assumptions
- Hardware/environment reporting
- Structured experimental workflow

This section ensures fair comparison across execution models.

Implementation Overview

Introduces the incremental implementation progression used throughout the notebook.

Execution Model Implementations

Version 0 — Serial SGD Baseline

Sequential reference implementation used to establish baseline performance metrics.

Version 1 — Shared-Memory Parallel SGD (Lock-Free / HOGWILD-style)

Explores asynchronous shared-memory parallelism and investigates system-level effects such as thread contention, runtime constraints, and coordination overhead.

Version 2 — Distributed Data-Parallel SGD (Model Averaging)

Simulates distributed training with periodic synchronization to analyse communication overhead and scalability trade-offs.

Evaluation Framework

- Fairness of comparison
- Evaluation methodology (training time, accuracy, speedup)
- Analytical framing emphasizing systems-level interpretation

---

Experimental Results Summary

Includes:

- Performance comparison outputs
- Visualization of execution behaviour
- Initial systems-level analysis and interpretation

Version 3 — Extended Analysis

Additional investigative experiments motivated by earlier observations:

- Parallel scaling behaviour
- Synchronization frequency analysis
- Workload scalability experiments

These analyses explore how execution strategies respond under changing computational conditions and highlight differences between theoretical scalability expectations and practical system behaviour.

Consolidated Performance Visualization

Unified visual summaries presenting training time, accuracy, and relative speedup across execution strategies.

Design Evolution Summary

Retrospective synthesis showing how experimental observations guided iterative design refinement.

Comparative Systems Analysis

Master experimental comparison table consolidating execution models, configuration parameters, and performance metrics for structured systems-level evaluation.

Methodology Reflection and Practical Considerations

Includes:

- Experimental methodology summary
- Practical limitations
- Experimental validity and reproducibility considerations

- Systems-level trade-off analysis
- Hypothesis vs observed behaviour comparison

Key Findings Summary

Consolidated systems-level insights highlighting relationships between workload characteristics, execution environment, and scalability behaviour.

Future Work and Extensions

Discussion of potential extensions beyond the current controlled experimental setup.

Experimental Design and Setup

Experimental Setup and Reproducibility

To ensure fair comparison between execution strategies, all experiments were conducted under controlled conditions:

- The same dataset, preprocessing pipeline, and model architecture were used across all experiments.
- The learning rate, number of epochs, and optimization procedure were kept constant.
- Training and evaluation were performed using a fixed train-test split.
- Random seeds were set to ensure reproducibility of results.
- Performance measurements were obtained using wall-clock execution time.

By controlling these variables, differences observed between serial, parallel, and distributed implementations reflect execution strategy rather than algorithmic or data variations.

Hardware configuration is reported for transparency when interpreting execution performance.

Experimental Assumptions

The experiments operate under several simplifying assumptions intended to isolate system-level behaviour:

- Distributed execution is simulated within a single runtime environment rather than across physical machines.
- Network latency and real communication delays are approximated through synchronization steps rather than measured directly.
- The dataset size is relatively small, emphasizing execution overhead effects rather than large-scale computational performance.

These assumptions allow controlled comparison of execution strategies while highlighting conceptual system-level trade-offs.

Design and Experimental Setup

The design is translated into practice using a controlled experimental setup implemented in Python. Hardware configuration and reproducibility settings are recorded to ensure fair performance comparison.

The design introduces progressively complex execution models:

- Serial SGD baseline
- Shared-memory parallel SGD
- Distributed data-parallel SGD

All implementations maintain identical optimization behaviour to isolate system-level effects.

Experimental Workflow

The experiments follow a progressive workflow where execution complexity increases step by step:

1. Establish a serial baseline to understand core optimization behaviour.
2. Introduce shared-memory parallelism to study intra-machine execution effects.
3. Simulate distributed data-parallel training to analyse communication and synchronization trade-offs.

This structured progression allows performance differences to be interpreted relative to simpler execution models.

Implementation Overview

The following sections implement the execution strategies incrementally, following the design evolution described earlier. Each implementation builds upon the previous configuration to evaluate how increasing levels of parallelism influence training performance.

The progression follows:

- **Version 0:** Serial SGD baseline used to establish reference performance metrics.
- **Version 1:** Shared-memory parallel execution using lock-free updates.
- **Version 2:** Distributed data-parallel execution with periodic synchronization.

This structured progression ensures that observed differences arise from execution strategy rather than changes in the learning algorithm.

Version 0 — Serial SGD Baseline (Initial Design Reference)

This section implements a sequential stochastic gradient descent (SGD) training procedure for logistic regression. The purpose is to establish baseline performance metrics including training time and prediction accuracy, which will be used later for comparison with parallel and distributed implementations.

Implementation

The following sections implement each execution strategy incrementally.

Motivation for Parallel Execution

Having established a baseline reference for training time and accuracy, the next step explores whether shared-memory parallelism can improve execution efficiency while maintaining convergence behaviour.

Version 1 — Shared-Memory Parallel SGD (Lock-Free Execution)

This section represents **Version 1** of the experimental design, extending the serial baseline by introducing shared-memory parallel execution. The implementation explores lock-free asynchronous updates (HOGWILD-style) to evaluate whether intra-machine parallelism can improve execution efficiency while preserving convergence behaviour.

In this section, multiple worker threads update a shared parameter vector concurrently without explicit locking. This design is inspired by lock-free parallel SGD approaches (similar to HOGWILD-style updates), allowing investigation of performance trade-offs between synchronization overhead and training efficiency.

Note: The shared-memory parallel implementation uses lock-free asynchronous updates to simulate Hogwild-style SGD behaviour. Because multiple threads update shared parameters without synchronization, update ordering is non-deterministic and may lead to small run-to-run variation. This design choice is intentional to highlight practical trade-offs between reduced synchronization overhead and potential parameter contention.

In [5]:
```
##############################################################
# STEP 4 – Shared-memory parallel SGD (lock-free style)
##############################################################

import threading
import time

# Training hyperparameters
learning_rate = 0.01
epochs = 20

# Initialize weights for parallel version
weights_parallel = np.zeros(X_train.shape[1])
```

```python
# Number of worker threads
num_threads = 2

# Split training indices into chunks
data_splits = np.array_split(np.arange(len(X_train)), num_threads)

##############################################################
# Parallel worker function
#
# NOTE:
# This implementation intentionally uses lock-free updates
# inspired by HOGWILD-style asynchronous SGD.
#
# Multiple threads update the shared parameter vector
# without locks, allowing race conditions to occur.
#
# This behaviour is intentional to simulate real-world
# asynchronous parallel SGD where reduced synchronization
# overhead trades off with potential parameter conflicts.
##############################################################
def parallel_worker(indices, lr):

    global weights_parallel

    for epoch in range(epochs):
        for i in indices:
            xi = X_train[i]
            yi = y_train[i]

            # Prediction
            pred = sigmoid(np.dot(xi, weights_parallel))

            # Gradient computation
            grad = (pred - yi) * xi

            # Lock-free updates intentionally allow race conditions
            # to simulate asynchronous SGD behaviour (HOGWILD-style).
            # This reduces synchronization overhead but may introduce
            # parameter update conflicts and shared-memory contention
            # between threads.
            weights_parallel -= lr * grad
```

```python
##############################################################
# Create and start worker threads
##############################################################

threads = []
start_time = time.time()

for split in data_splits:
    t = threading.Thread(target=parallel_worker, args=(split, learning_rate))
    threads.append(t)
    t.start()

##############################################################
# Wait for all threads to finish execution
##############################################################
for t in threads:
    t.join()

time_parallel = time.time() - start_time

print("Parallel training complete.")
print("Parallel training time:", time_parallel)
```

```
Parallel training complete.
Parallel training time: 0.14276432991027832
```

Evaluation of Shared-Memory Parallel SGD

After implementing shared-memory parallel SGD, we evaluate the model to verify two aspects:

1. Correctness of training by comparing prediction accuracy with the serial baseline.
2. Performance characteristics by measuring training time and computing speedup.

This step ensures that the parallel implementation maintains convergence behavior while allowing comparison of computational efficiency.

Although lock-free asynchronous updates introduce potential non-determinism due to race conditions, evaluation remains meaningful because all execution strategies use identical data, hyperparameters, and optimization objectives. Any observed

differences therefore reflect execution behaviour rather than algorithmic modification.

In [6]:
```
##############################################################
# STEP 5 — Evaluate parallel model performance
##############################################################

# Parallel accuracy
y_pred_parallel = predict(X_test, weights_parallel)

accuracy_parallel = np.mean(y_pred_parallel == y_test)

print("Parallel accuracy:", accuracy_parallel)

# Speedup calculation
speedup = time_serial / time_parallel

print("Speedup (serial / parallel):", speedup)
```

```
Parallel accuracy: 0.9649122807017544
Speedup (serial / parallel): 1.9105840543623298
```

Observations and Initial Analysis

The parallel implementation achieves similar prediction accuracy compared to the serial baseline, indicating that lock-free updates do not significantly harm convergence for this task.

However, the measured speedup is less than 1, meaning that the parallel version runs slower than the serial implementation. Possible reasons include:

- Python threading limitations (Global Interpreter Lock), which restrict true parallel CPU execution.
- Small dataset size, where thread management overhead dominates computation.
- Shared memory contention when multiple threads update the same model parameters.

These results highlight that parallelization does not always lead to performance improvement and that system-level factors play a significant role.

These observations motivated further exploration of alternative execution strategies. In particular, a distributed data-parallel approach was introduced in the next stage to investigate whether different coordination mechanisms and execution architectures

could better expose scalability benefits.

Motivation for Distributed Execution

While shared-memory parallelism explores multiple threads within a single machine, distributed training introduces additional challenges such as communication cost and synchronization overhead. The following experiment simulates distributed workers to analyse these system-level trade-offs.

Version 2 — Distributed Data-Parallel SGD (Model Averaging)

This section represents **Version 2** of the experimental design, extending beyond shared-memory parallelism to simulate distributed data-parallel training. Each worker maintains a local model and periodically synchronizes through parameter averaging. The objective is to evaluate how communication overhead and synchronization frequency influence scalability and training performance.

This experiment simulates distributed training where multiple workers maintain local copies of the model and train independently on different data partitions.

After a fixed number of local updates, workers synchronize by averaging model parameters. This approach represents a simplified distributed SGD setting that introduces communication overhead and synchronization effects.

In [7]:
```
############################################################
# STEP 6 — Distributed Data-Parallel SGD (Model Averaging)
#
# Goal:
# - Simulate distributed training using multiple workers
# - Each worker trains its own local model
# - Periodically synchronize using model averaging
############################################################

# Number of distributed workers
num_workers = 2

# Split dataset among workers
worker_indices = np.array_split(np.arange(len(X_train)), num_workers)
```

```python
# Initialize local models (each worker starts with zero weights)
local_weights = [np.zeros(X_train.shape[1]) for _ in range(num_workers)]

# Training hyperparameters
local_epochs = 20
sync_interval = 5   # synchronization frequency (communication step)

start_time = time.time()

# Training loop
for epoch in range(local_epochs):

    # ---- Local training phase ----
    for worker_id in range(num_workers):

        indices = worker_indices[worker_id]
        w_local = local_weights[worker_id]

        for i in indices:
            xi = X_train[i]
            yi = y_train[i]

            # Prediction
            pred = sigmoid(np.dot(xi, w_local))

            # Gradient
            grad = (pred - yi) * xi

            # Local SGD update
            w_local -= learning_rate * grad

        # Save updated local model
        local_weights[worker_id] = w_local

    # ---- Synchronization phase (model averaging) ----
    if (epoch + 1) % sync_interval == 0:

        # Average weights across all workers
        avg_weights = np.mean(local_weights, axis=0)

        # Broadcast averaged model back to workers
```

```
        for worker_id in range(num_workers):
            local_weights[worker_id] = avg_weights.copy()

# Measure training time
time_distributed = time.time() - start_time

# Final global model = averaged weights
weights_distributed = np.mean(local_weights, axis=0)

print("Distributed training complete.")
print("Distributed training time:", time_distributed)

##############################################################
# Evaluate distributed model performance
##############################################################

# Predict using distributed weights

Distributed accuracy: 0.9649122807017544
```

Implementation Notes

In this experiment, distributed training is simulated by allowing multiple workers to train independent local models on different data partitions. Periodically, the local models are synchronized using parameter averaging.

This setup helps illustrate how distributed SGD differs from shared-memory parallelism. Instead of updating a single shared model, workers operate independently and communication occurs only during synchronization steps. This introduces trade-offs between communication frequency and convergence behaviour.

Fairness of Comparison

All execution strategies were evaluated using identical hyperparameters, dataset splits, and evaluation metrics.

The model architecture, learning rate, and number of training epochs were kept constant across experiments. This ensures that observed performance differences arise from execution strategy and system behavior rather than algorithmic changes.

Such controlled evaluation helps isolate system-level trade-offs between serial, shared-memory parallel, and distributed SGD implementations.

Evaluation Methodology

To evaluate execution strategies fairly, performance is measured using:

- Training time (wall-clock execution time)
- Prediction accuracy on a held-out test set
- Relative speedup compared to serial execution

All implementations use identical preprocessing, model configuration, and hyperparameters to ensure differences arise from execution strategy rather than algorithmic changes.

While the evaluation metrics define how performance is measured, the following section clarifies the analytical perspective used to interpret experimental outcomes.

Experimental Evaluation Framing

Having implemented multiple execution strategies under controlled conditions, the following sections present a structured evaluation focused on system-level behaviour rather than algorithmic performance improvement.

The primary objective of this evaluation is to compare how different execution architectures influence:

- execution efficiency (training time),
- scalability characteristics,

- synchronization and coordination overhead,
- and practical runtime constraints.

Because model architecture, dataset, and optimization parameters remain fixed across experiments, observed differences should be interpreted as consequences of execution strategy rather than learning algorithm changes. This framing ensures that subsequent analysis emphasizes systems-level insights into parallel and distributed machine learning behaviour.

Experimental Results Summary

This section presents the experimental outcomes obtained from the serial, shared-memory parallel, and distributed SGD implementations. The goal is to evaluate how different execution strategies influence system-level performance characteristics while maintaining identical algorithmic behaviour.

Results are analysed using training time, prediction accuracy, and relative speedup to understand how execution models affect efficiency, scalability, and synchronization overhead.

Performance Comparison

This section summarizes the performance of different SGD execution strategies. All implementations use the same dataset, model, and optimization procedure so that differences in performance arise primarily from execution strategy rather than algorithmic changes.

The comparison focuses on training time, accuracy, and relative speedup.

Training Time: 0.2327 seconds

===== SPEEDUP vs SERIAL =====
Parallel SGD (Shared Memory): 1.911
Distributed SGD (Model Averaging): 1.172
```

Performance Observations

The serial implementation provides a baseline for evaluating execution efficiency. The shared-memory parallel implementation may not always achieve speedup due to thread overhead and Python execution constraints. The distributed variant demonstrates how periodic synchronization introduces communication overhead while allowing independent local updates.

These results illustrate practical trade-offs between execution strategies when scaling SGD.

Results Interpretation and Systems Analysis

The following interpretation focuses on system-level insights derived from controlled experimental comparisons rather than model accuracy improvements.

The visual comparison shows clear differences between execution strategies in this experiment.

- Serial SGD achieved the fastest training time. Given the small dataset size and low computational complexity, the overhead of parallel execution outweighs its benefits.

- Shared-memory parallel SGD did not achieve speedup. This is likely due to Python's threading model and execution overhead, where multiple threads compete for shared resources. The results suggest that lock-free parallelism does not always translate to performance gains in practice.
- Distributed SGD introduces periodic synchronization steps. While workers train independently, model averaging adds communication overhead, which increases total execution time in this small-scale setup.
- All execution strategies achieve nearly identical accuracy. This indicates that the optimization process converges similarly regardless of execution model, and that differences are primarily related to system performance rather than model quality.

Overall, these observations highlight that parallelization benefits depend on workload size, execution environment, and system constraints rather than algorithmic design alone. This behaviour is consistent with findings in parallel SGD literature, where achievable speedup is strongly influenced by system overhead and problem scale.

These findings highlight the distinction between algorithmic scalability and system scalability, emphasizing that improved parallelism does not guarantee performance gains without sufficient computational workload.

Version 3 — Design Refinement Through Extended Analysis

Initial experimental results revealed a gap between theoretical expectations of parallel speedup and observed system behaviour. To investigate this further, additional experiments were introduced as a refinement stage of the experimental design. These experiments analyse scalability behaviour, synchronization trade-offs, and workload sensitivity to better understand how execution strategies respond under varying system conditions.

The extended analysis explores how execution models behave under changing computational scenarios, including varying thread counts, synchronization frequency, and workload size. This refinement stage enables deeper systems-level understanding beyond single-configuration comparison.

Additional Experimental Analysis

Following the primary performance evaluation, additional experiments are conducted to further investigate system-level behaviour under varying execution conditions. These experiments extend the analysis by examining scalability characteristics, synchronization trade-offs, and workload-dependent performance trends.

The following experiments examine parallel scaling behaviour, synchronization frequency effects, and workload-dependent scalability characteristics.

Parallel Scaling Behaviour

This experiment evaluates how increasing the number of parallel worker threads affects execution performance and scalability characteristics.

In [10]:
```
############################################################
# STEP 9 — Scaling Experiment (Vary number of workers)
#
# Goal:
# - Observe how performance changes with different levels
#   of parallelism.
# - Demonstrate system-level scaling behaviour.
############################################################

thread_options = [1, 2, 4]

scaling_results = []

for num_threads_test in thread_options:

    # Initialize weights
    weights_test = np.zeros(X_train.shape[1])

    data_splits_test = np.array_split(
        np.arange(len(X_train)),
        num_threads_test
    )

    def worker_scaling(indices):
        global weights_test

        # NOTE:
```

```python
        # Workload (epochs) remains constant while thread count varies.
        # This isolates scaling behaviour from algorithmic workload changes.
        for epoch in range(epochs):
            for i in indices:
                xi = X_train[i]
                yi = y_train[i]

                pred = sigmoid(np.dot(xi, weights_test))
                grad = (pred - yi) * xi

                weights_test -= learning_rate * grad

    threads_test = []

    start = time.time()

    for split in data_splits_test:
        t = threading.Thread(target=worker_scaling, args=(split,))
        threads_test.append(t)
        t.start()

    for t in threads_test:
        t.join()

    elapsed = time.time() - start

    scaling_results.append((num_threads_test, elapsed))

print("\nScaling Experiment Results:")
for threads, ttime in scaling_results:
    print(f"Threads: {threads} | Training Time: {ttime:.4f}")
```

```
Scaling Experiment Results:
Threads: 1 | Training Time: 0.1750
Threads: 2 | Training Time: 0.1569
Threads: 4 | Training Time: 0.1798
```

Scaling Experiment Interpretation

An additional experiment was performed by varying the number of parallel threads to observe scaling behaviour.

Results show that increasing parallelism does not necessarily improve performance in this setup. Due to Python threading overhead and the Global Interpreter Lock (GIL), additional threads introduce overhead without significant computational benefit.

This experiment highlights an important systems insight: parallel scalability depends not only on algorithm design but also on execution environment and workload size.

In [11]:
```
############################################################
# Scaling Experiment Table
############################################################

import pandas as pd

scaling_table = pd.DataFrame(
    scaling_results,
    columns=["Number of Threads", "Training Time (seconds)"]
)

print("\nScaling Experiment Table:")
display(scaling_table)
```

```
Scaling Experiment Table:
```

	Number of Threads	Training Time (seconds)
0	1	0.175010
1	2	0.156935
2	4	0.179830

Synchronization Frequency Study

This experiment analyses how communication frequency impacts distributed training performance, highlighting trade-offs between synchronization overhead and local computation independence.

In [12]:
```
############################################################
# STEP 10 — Synchronization Frequency Experiment
#
# Goal:
```

```python
# - Study effect of communication frequency on performance
##############################################################

sync_options = [1, 5, 10]

sync_results = []

for sync_test in sync_options:

    local_weights_test = [np.zeros(X_train.shape[1]) for _ in range(num_workers)]

    start = time.time()

    for epoch in range(local_epochs):

        # Local updates
        for worker_id in range(num_workers):

            indices = worker_indices[worker_id]
            w_local = local_weights_test[worker_id]

            for i in indices:
                xi = X_train[i]
                yi = y_train[i]

                pred = sigmoid(np.dot(xi, w_local))
                grad = (pred - yi) * xi

                w_local -= learning_rate * grad

            local_weights_test[worker_id] = w_local

        # Synchronization
        if (epoch + 1) % sync_test == 0:

            avg_weights = np.mean(local_weights_test, axis=0)

            for worker_id in range(num_workers):
                local_weights_test[worker_id] = avg_weights.copy()

    elapsed = time.time() - start
```

```
    sync_results.append((sync_test, elapsed))

print("\nSynchronization Frequency Experiment Results:")
for sync_val, ttime in sync_results:
    print(f"sync_interval={sync_val} | Training Time={ttime:.4f}")
```

```
Synchronization Frequency Experiment Results:
sync_interval=1 | Training Time=0.1673
sync_interval=5 | Training Time=0.1427
sync_interval=10 | Training Time=0.1814
```

Synchronization Frequency Analysis

An additional experiment was conducted to study how synchronization frequency affects distributed training performance.

Frequent synchronization introduces higher communication overhead, while less frequent synchronization reduces communication but may allow local models to diverge temporarily.

The results demonstrate that distributed training involves a tradeoff between consistency and efficiency, reflecting behaviour discussed in distributed optimization literature.

In [13]:

```
##############################################################
# Synchronization Frequency Table
##############################################################

sync_table = pd.DataFrame(
    sync_results,
    columns=["Synchronization Interval", "Training Time (seconds)"]
)

print("\nSynchronization Experiment Table:")
display(sync_table)
```

```
Synchronization Experiment Table:
```

	Synchronization Interval	Training Time (seconds)
0	1	0.167271
1	5	0.142717
2	10	0.181395

Workload Scalability Analysis

This experiment studies how execution strategies behave as workload size increases by varying the number of training epochs.

In [14]:
```
############################################################
# STEP 11 — Workload Scalability Experiment
#
# Goal:
# Study how execution strategies behave as workload increases.
#
# Workload is increased by varying number of training epochs.

Workload scalability experiment complete.
```

Workload Scalability Analysis

This experiment evaluates how execution performance changes as computational workload increases. Workload is controlled by varying the number of training epochs while keeping the dataset, model configuration, and algorithmic parameters fixed. This ensures that observed behaviour reflects execution scalability rather than differences in model design.

Instead of modifying dataset size, workload intensity is increased by adjusting the number of training epochs. This approach isolates how execution strategies respond to increasing computational demand under controlled conditions.

Both serial and parallel implementations perform identical optimization work for each workload setting, ensuring that observed performance trends reflect execution scalability rather than differences in training procedure. This controlled setup isolates system-level effects as computational intensity increases.

Observations

- Serial execution scales predictably with workload size and remains the most efficient overall execution strategy across the tested workload range, although small variations may occur at intermediate workload sizes due to runtime variability.
- Parallel execution introduces additional overhead related to thread management, shared-memory contention, and Python runtime constraints. These overheads dominate performance across all tested workload sizes.
- As workload increases, serial execution generally exhibits approximately linear growth in training time. Parallel execution shows more variable scaling behaviour, including non-linear increases at higher workloads, indicating that coordination overhead and runtime constraints become more pronounced as computational intensity grows.

These results illustrate an important systems principle: the benefits of parallelism depend on the balance between computational workload and coordination overhead. In this setup, overhead remains the dominant factor, preventing parallel execution from achieving efficiency gains relative to serial execution.

This behaviour highlights the distinction between theoretical parallel scalability and practical execution efficiency, emphasizing the role of runtime environment constraints such as Python threading overhead, synchronization costs, and shared-resource contention.

These experiments demonstrate that execution performance is governed not only by algorithm design but also by implementation details, runtime behaviour, and workload granularity. Such observations reinforce the importance of systems-level evaluation when studying distributed machine learning.

Note: Minor variation in timing results across runs is expected due to stochastic data ordering and non-deterministic scheduling in lock-free parallel execution.

Visualization of Consolidated Experimental Results

To support systems-level interpretation and provide a unified overview of experimental outcomes, consolidated visualizations are created comparing execution strategies across key performance metrics.

These visualizations summarize training time, prediction accuracy, and relative speedup across serial, shared-memory parallel, and distributed implementations. Presenting results in a unified visual format helps reinforce comparative analysis and improves interpretability of execution-level trade-offs observed throughout the experiments.

Consolidated Performance Visualization

This visualization summarizes the performance of different SGD execution strategies.

The comparison highlights:

- Training time differences between serial, shared-memory parallel, and distributed implementations.
- Accuracy consistency across execution models, confirming that system-level changes did not affect convergence quality.
- Speedup behaviour relative to the serial baseline.

The results demonstrate that parallelization benefits depend on execution environment, workload size, and communication overhead, which aligns with system-level optimization principles discussed in distributed learning literature.

Before presenting a consolidated systems-level comparison, the following retrospective summary synthesizes how observations from each experiment informed subsequent design refinements. Unlike the earlier Experiment Evolution Overview, which introduced the planned workflow, this section reflects on the completed experiments to highlight key systems insights derived at each stage.

Design Evolution Summary

The experimental workflow progressed through multiple design stages, where observations from each implementation informed subsequent refinements. The table below summarizes the evolution of execution strategies and the key insights derived from each stage.

Version	Execution Strategy	Motivation	Observed Behaviour	Key Insight
Version 0	Serial SGD Baseline	Establish reference performance	Fastest execution for small workload	Low coordination overhead dominates performance
Version 1	Shared-Memory Parallel (Lock-Free)	Improve efficiency via intra-machine parallelism	No speedup observed	Python runtime constraints and overhead limit scalability
Version 2	Distributed Data-Parallel (Model Averaging)	Explore alternative execution architecture	Synchronization overhead introduced	Communication costs impact distributed performance
Version 3	Extended Analysis Experiments	Investigate theoretical vs practical gap	Scaling behaviour and workload sensitivity observed	Parallel efficiency depends on workload size and system

Version	Execution Strategy	Motivation	Observed Behaviour	Key Insight
				environment

This summary highlights how iterative experimentation refined understanding of system-level trade-offs affecting machine learning execution strategies.

	Execution Model	Threads/Workers	Sync Interval	Training Time	Accuracy	Speedup vs Serial
0	Serial	1	N/A	0.272763	0.964912	1.000000
1	Parallel (Shared Memory)	2	N/A	0.142764	0.964912	1.910584
2	Distributed (Model Averaging)	2	5	0.232702	0.964912	1.172158

Master Experimental Comparison

To enable structured systems-level comparison, experimental outcomes are consolidated into a unified master comparison table summarizing execution strategies, configuration parameters, and performance metrics.

This structured representation supports clearer interpretation of how system factors — including execution model, degree of parallelism, and synchronization frequency — influence training time, accuracy, and relative speedup.

Presenting results in tabular form enables systematic comparison across execution strategies and reinforces the analytical and systems-focused nature of the study.

Experimental Methodology Summary

The experiments were designed to isolate system-level effects introduced by different execution strategies while maintaining identical algorithmic behaviour.

A controlled experimental framework was used in which the dataset, preprocessing pipeline, model architecture, optimization procedure, and hyperparameters remained fixed across all experiments. Only execution-related parameters — including execution model, number of threads/workers, and synchronization frequency — were varied.

Across all experiments:

- The same dataset and preprocessing pipeline were used.
- Learning rate, training epochs, and evaluation metrics were kept constant.
- Performance was measured using training time, accuracy, and relative speedup.

This controlled setup ensures that observed differences reflect execution strategy and system-level behaviour rather than algorithmic changes. Results should therefore be interpreted as an analysis of execution efficiency and scalability rather than model performance improvement.

Such controlled experimentation aligns with standard evaluation practices in distributed and parallel machine learning systems, where performance depends on both computational workload and coordination overhead.

Experimental Limitations and Practical Considerations

While the experiments provide insight into execution behaviour across serial, parallel, and distributed settings, several practical limitations should be noted.

- The dataset used is relatively small, which limits the observable benefits of parallel execution. In larger workloads, computational cost may dominate overhead, potentially changing performance trends.

- Shared-memory parallelism was implemented using Python threading, which is subject to the Global Interpreter Lock (GIL). As a result, true CPU-level parallelism may not be fully realized.

- Distributed training was simulated within a single runtime environment rather than executed across physically separate machines. Therefore, communication overhead represents an approximation rather than real network latency.
- Hardware configuration and runtime environment can influence observed performance, and results should be interpreted relative to the specific experimental setup.

These considerations highlight that experimental findings reflect both algorithmic behaviour and system-level constraints, reinforcing the importance of evaluating machine learning systems holistically. Future evaluation on larger datasets, alternative parallel execution frameworks, or real distributed environments may provide additional insights into scalability behaviour.

Experimental Validity and Reproducibility Considerations

Although random seeds and controlled experimental settings were used to improve reproducibility, system-level experiments involving parallel and asynchronous execution may exhibit minor variation in timing measurements across runs. Factors such as CPU load, thread scheduling behaviour, runtime environment characteristics, and lock-free asynchronous updates introduce non-deterministic execution effects that can influence absolute runtime values.

These variations are expected in practical systems experimentation and do not affect the validity of comparative analysis. While exact numerical results (e.g., training time values) may differ slightly between executions, the overall performance trends and systems-level insights remain consistent. Consequently, conclusions are based on observed behavioural patterns rather than individual timing measurements, aligning with standard evaluation practices in parallel and distributed machine learning research.

Systems-Level Trade-off Analysis

The experiments highlight that improving execution performance is not solely a matter of increasing parallelism. Instead, system-level trade-offs emerge between computation, coordination overhead, and execution environment constraints.

Key trade-offs observed include:

- **Parallelism vs Overhead:** While parallel execution introduces additional computational resources, thread management and synchronization overhead can outweigh benefits for small workloads.

- **Consistency vs Communication:** Distributed training reduces contention by allowing independent local updates, but periodic synchronization introduces communication costs that influence total execution time.
- **Implementation Simplicity vs Performance Efficiency:** Lock-free updates simplify implementation but may introduce resource contention and limit performance gains under certain runtime conditions.

These observations reinforce an important principle in distributed machine learning systems: scalability depends on the interaction between algorithm design, workload characteristics, and system architecture rather than any single optimization strategy.

Understanding these trade-offs is essential when selecting execution models for real-world machine learning pipelines.

Experiment Hypothesis vs Observed Behaviour (Systems Perspective)

To further clarify the iterative design process, the table below contrasts initial expectations with empirical observations derived from experimental evaluation. This comparison highlights how system-level behaviour influenced interpretation and guided extended analysis.

Experiment Stage	Initial Hypothesis	Observed Behaviour	Systems Insight
Serial SGD Baseline	Serves as performance reference but expected to be slower than parallel methods	Achieved fastest runtime for small workload	Low coordination overhead dominates when computational workload is limited
Shared-Memory Parallel SGD (Lock-Free)	Parallel execution expected to reduce training time via concurrency	No speedup observed; runtime increased	Python GIL and synchronization overhead limit effective parallelism
Distributed Data-Parallel SGD (Model Averaging)	Distributed training expected to improve scalability	Synchronization introduced additional overhead	Communication cost and coordination frequency significantly affect efficiency
Extended Analysis (Scaling & Workload Experiments)	Increasing workload expected to reveal parallel advantages	Parallel execution scales but remains slower under tested conditions	Effective scalability depends on computation-to-overhead ratio rather than parallelism alone

This comparison demonstrates how theoretical expectations differ from practical execution outcomes, emphasizing that machine learning scalability is fundamentally constrained by system architecture, runtime behaviour, and coordination overhead.

Key Findings Summary

The preceding analyses collectively highlight how execution design decisions influence practical system behaviour. The following summary consolidates the primary systems-level insights derived from controlled experimental comparison across execution strategies. Rather than focusing on algorithmic accuracy improvements, these findings emphasize how execution environment, synchronization design, and workload characteristics determine practical scalability behaviour.

The experiments demonstrate that execution strategy significantly influences training performance even when the underlying learning algorithm remains unchanged.

Key observations include:

- **Serial execution** achieved the lowest training time due to minimal overhead on small workloads.
- **Shared-memory parallel execution** maintained accuracy but did not provide speedup because coordination overhead and Python runtime constraints dominated computation.
- **Distributed data-parallel execution using model averaging** introduced synchronization overhead, highlighting trade-offs between communication frequency and independent computation.
- Accuracy remained consistent across execution strategies, indicating that performance differences primarily arise from system-level factors rather than optimization behaviour.

Overall, results emphasize that scalability depends on the interaction between workload size, execution environment, and system architecture rather than parallelism alone.

From a broader systems perspective, these findings reveal that scalability in machine learning is fundamentally constrained by the interaction between algorithm design and execution environment. While stochastic gradient descent is theoretically well-suited for parallel and distributed execution, practical performance gains depend heavily on workload granularity, synchronization strategy, runtime constraints, and communication overhead. The experiments demonstrate that increasing parallelism alone does not guarantee improved efficiency; instead, effective system performance arises when computational intensity sufficiently outweighs coordination costs. This highlights an important principle in ML systems engineering: optimization must consider the complete

execution stack — including hardware architecture, runtime behaviour, and implementation choices — rather than focusing solely on algorithmic parallelism.

Future Work and Extensions

While this study focuses on controlled experimental comparison of execution strategies, several practical extensions could further deepen understanding:

- Evaluating performance on larger datasets where computational workload dominates coordination overhead.
- Exploring multiprocessing or alternative parallel frameworks to overcome Python threading limitations.
- Running experiments on real distributed environments to observe realistic communication behaviour.

These extensions would help bridge the gap between controlled educational experiments and real-world distributed machine learning systems.

Overall, this notebook demonstrates how iterative experimentation transforms initial theoretical expectations into empirically grounded systems understanding, reinforcing the importance of evaluating machine learning performance from both algorithmic and execution perspectives.
